# Exercise 03: The randomised perceptron learning rule

We consider a more general case of a perceptron in this exercise.

- First of all, we consider a **teacher-student** scenario, which is more general and allows us to better explain the nuts and bolts of the learning process.
- Also, we set an N generic number of (obviously even) elements of the input vector.
- We make learning noisy, by adding a random Gaussian term to the learning rule.

### Step 1: Use the perfect perceptron as T

The basic setting is the following: we have a teacher perceptron, which in our case will be the already seen *perfect perceptron*. The perceptron is given by

$$\sigma(\vec{\xi}^{\mu}, \vec{J}) = \operatorname{sign}(\vec{\xi}^{\mu} \cdot \vec{J})$$

and the weights of the perfect perceptron are  $J_i^* = 2^{N/2-i}$  in the first half of the weights vector and the same numbers but of the opposite sign in the rest.

#### Step 2: Initialise a student perceptron with random weights

In the **training** part, the initial weights will be initialised at random for the student perceptron. It will be attempting learning from the teacher perceptron by applying a learning rule, which is in our case

$$\vec{J}(t+1) = \vec{J} + \frac{1}{\sqrt{N}} \sigma_T^{\mu} \vec{\xi}^{\mu} (1+\vec{r})$$

where  $r \sim \mathcal{N}(0, \sqrt{50})$ .

```
Currently N is 20 and the weights of the perfect perceptron are:
[ 512.
        256.
               128.
                       64.
                              32.
                                     16.
                                             8.
                                                   4.
                                                          2.
                                                                 1. -512. -256.
 -128.
        -64.
               -32.
                      -16.
                              -8.
                                     -4.
                                           -2.
                                                  -1.]
```

## Step 3 and 4: produce sets for different P values and train the student perceptron

Now we generate the training sets. We will do this for a set of different P values: 1, 10, 20, 50, 100, 150, 200. The goal is to understand whether we get an improvement in the learning process whenever we have a bigger training set size.

For each value of P, we do the following:

- set up a random vector of weights
- generate a random 0/1 matrix of size  $P \times N$
- get the true values  $\sigma_T^{\mu}$  for each  $\mu$ -th vector by passing the  $\xi^{\mu}$  vector to the perfect perceptron (now this will be the teacher perceptron)
- iterate over variable t, that we max-bounded at 10000 in order to avoid cycles that are too long, looking for the situation in which the training error  $\epsilon_t = 0$
- At each time t, iterate over the μ-th data point and check whether the given weights (initalised at random) gives us the same results wrt those given by the teacher perceptron.
   If not, we correct the weights vector with a term given by the learning rule above.

What we would expect is that with bigger training sets the generalisation works better, and students are better able to reproduce the behaviour of the teacher since they are *exposed* more often to what is right and what is wrong.

```
Training for P = 1 converged in time 1
Training for P = 10 converged in time 58
Training for P = 20 converged in time 207
Training for P = 50 converged in time 168
Training for P = 100 converged in time 1295
Training for P = 150 converged in time 372
Training for P = 200 converged in time 2066
```

In ascending order of P weight vectors are

```

                 -26.32,
                                                6.11,
                                                        31.86])]
```

### Step 5: Evaluate single instance test error for 1000 elements

Now that we have trained the student perceptrons, we want to test them against out-of-sample data. We show now the results for a single instance of the  $P_{test} = 1000$  case.

```
On a single instance:

- the test error for P = 1 is 0.505

- the test error for P = 10 is 0.415

- the test error for P = 20 is 0.383

- the test error for P = 50 is 0.238

- the test error for P = 100 is 0.109

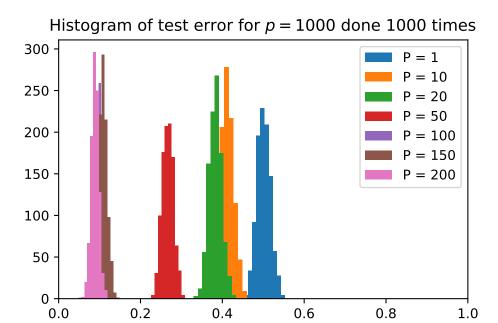

- the test error for P = 150 is 0.089

- the test error for P = 200 is 0.077
```

We can clearly see that there is a particular behaviour as P increases, in particular we see that the training error is decreasing. What happens if we do this many times? How will the training error be distributed over, say, a 1000 instantiations of the test?

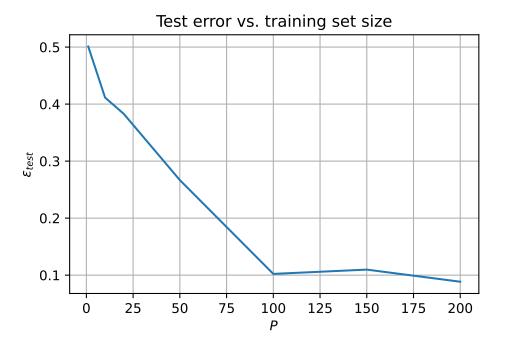

### Step 6: Do this 1000 times and evaluate the average test error

We can plot histograms of the result and see the distributions of test errors over a set of different P values. This result doesn't come as totally unexpected: the bigger the training set, the lesser the errors we make. We could also see a hint of this by seeing that array elements of higher P weight vectors were more and more similar to those of the perfect perceptron.

Step 7: Plot  $\epsilon$  vs. P

Now let us clearly state this by plotting the behaviour of the averages of the test error with respect to the progressively increasing size of the training set. As previously stated, it is unexpectedly decreasing.

Step 8: Repeat Steps 3-6 again but with N=40

Also notice that this time P values are 1, 2, 20, 40, 100, 200, 300.

```
Currently N is 40 and the weights of the perfect perceptron are:

```

On a single instance:

```
- the test error for P = 1 is 0.559
- the test error for P = 2 is 0.493
- the test error for P = 20 is 0.453
- the test error for P = 40 is 0.321
- the test error for P = 100 is 0.181
- the test error for P = 200 is 0.133
- the test error for P = 300 is 0.082
```

### Histogram of test error for p = 1000 done 1000 times

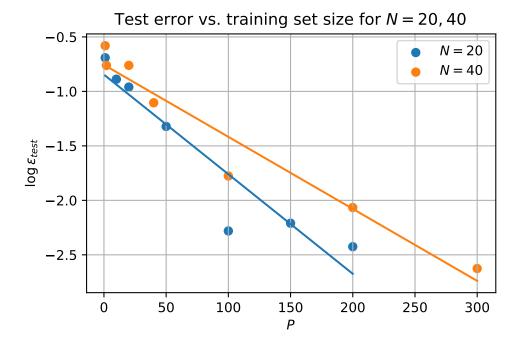

Step 9: Plot  $\epsilon$  vs. P for N=40,20

Let us compare the two plots.

Step 10: Find a way to represent the data

As we hinted in the plot below, we may make the hypothesis that the reduction of error with increasing P is an **exponential decay**, and compare the slopes for different sizes N of the input vector. To attain this we might fit the log curves in order to linearise the exponential behaviour and compare the slopes.

The slopes are -0.009140784504844015 -0.006610259193432749The inverse of the slopes (decay time in terms of P) are 109.39980036396939 151.2799983688226939

As the size N of input vectors increases, the error decay is reached for higher values of the training set size P. In particular for double the size of the input vector, the decay time nearly doubles (it is actually slightly more than the double).

This is what we expect from the fact that (see, for example, Engel & Van den Broek p. 12):

$$P = \alpha N$$

where  $\alpha$  is of order 1. It is a bit dangerous to make assumptions from two data points (with no regards whatsoever to the propagation of errors, either), but if the latter statement holds we can clearly see that  $P_{typical}$  grows linearly with N. In our case  $\alpha$  would have a value of

 $\alpha \sim 4.6$ 

Alphas for N=20 and N=40 are 5.4699900181984695 3.781999959220562
